ABSTRACT

Objectives: The present study was planned to evaluate the varying clinico–hematological manifestations in 50 children diagnosed as megaloblastic anemia over a four year period. An attempt has been made to find out relative prevalence of cobalamin and folate deficiency in children with megaloblastic anemia.

Material and Methods: All anemic children with or without bleeding manifestations had their peripheral blood smear examined. Complete hemogram including platelet count and mean corpuscular volume (MCV) were carried out in each child using Coulter counter.

Results: This study shows that in any malnourished and anemic child presenting with bleeding manifestations, a strong suspicion of megaloblastic anemia should be entertained. Anemia is not the only problem in these children, as is evident from the finding of neutropenia and thrombocytopenia. Also cobalamin deficiency appears to be emerging as a significant contributor to nutritional megaloblastic anemia. J Med Sci 2009;12(2):49–52

Keywords: Megaloblastic anemia, Cobalmin, Folate, Thrombocytopenia

Introduction

Anemias are the most important disorders of blood in infancy and early childhood. These result in significant morbidity and mortality in children and constitute a public health problem of considerable importance.1 Anemia is generally defined as a reduction in red cell mass or blood hemoglobin concentration characterized by decreased oxygen carrying capacity of blood which results in tissue anoxia producing various signs and symptoms. Anemia is not a diagnosis in itself but merely an objective sign of presence of disease. Anemia in children differs from those of adults as they tend to be more pronounced and develop rapidly. As much as 51% children in 0-4 years and 46% children 5-12 years are anemic in developing regions.2,3

Megaloblastic anemia is one of the important causes of anemias in children. It is not an infrequent entity in poor socioeconomic condition. Nutritional mega-loblastic anemia in children occurs commonly among undernourished or malnourished societies of tropical and subtropical countries. The commonest age is 3-18 months with maximum number of cases being in 9-12 months.2,4 These children are generally exclusively breast-fed by mothers who are undernourished and have poor blood levels of folate and cobalamin.5,7 This condition has protean manifestations in childhood, sometimes mimicking a hematological malignancy like leukemia. A great clinical importance is required in diagnosing this clinical entity as it responds to exceedingly well to treatment.

Folate deficiency is considered to be more important cause of megaloblastic anemia and very little emphasis has been given to cobalamin deficiency. Over the last three decades the prevalence of folate deficiency seems to have fallen from...
70-75% to 2-10% as reported in various studies in children and adults from different regions.\textsuperscript{67} Hence cobalamin deficiency appears to be emerging as a significant contributor to nutritional megaloblastic anemia.

The present study evaluates the varying clinicohematological manifestations in 50 children diagnosed as megaloblastic anemia over a four year period. In this study an attempt has been made to find out relative prevalence of cobalamin and folate deficiency in children with megaloblastic anemia.

**Subjects and Methods**

Fifty children (6 months - 6 years) diagnosed as megaloblastic anemia (hemoglobin less than 10g/dl, and MCV more than 90 fl) over a period of four year (May 2004 to April 2008) were prospectively studied. All anemic children with or without bleeding manifestations had their peripheral blood smear examined. Complete hemogram including platelet count and mean corpuscular volume (MCV) were carried out in each child using Coulter counter. All the cases with macrocytic blood picture were subjected to bone marrow examination to confirm the diagnosis of megaloblastic anemia. Serum $B_{12}$ and folic acid could be estimated by radioimmuno-assay in 29 children. The diagnosis of megaloblastic anemia was established on the basis of macrocytic PBF and megaloblastic bone marrow. Biochemically pure vitamin $B_{12}$ deficiency and folic acid deficiency were diagnosed when serum levels were below 80 pg/ml and 3ng/ml, respectively.\textsuperscript{57} Iron studies were done as an additional investigation for further ruling out concomitant iron deficiency.\textsuperscript{7} Relevant investigations were also done in case of various associated infections.

**Results**

The children were in the age group of 12 months to 16 years with male predominance (male : female ratio being 1:3:1). All the children belonged to peri-urban areas. About 23 children had normal nutritional status while 7, 6 and 4 children belonged to grade II, III and IV respectively as per IAP classification.

The varying clinical features are shown in Table 1. The peculiar features were 6(12%) presented with bleeding manifestations. The bleeding was mainly into the skin and subcutaneous tissue. Three children had epistaxis. Infantile tremor syndrome like features were seen in 3 (6%) children. All the children had pallor on examination. Hepatomegaly (up to 4cm) and spleno-megaly were seen in 19 (38%) and 5 (10%) respectively. There were no neurological deficits in any of the studied children.

The serum bilirubin levels ranged from 1.6 mg/dl to 3.4 mg/dl with predominance of indirect component thus suggesting mild hemolysis.

The children were put on oral folic acid (5 mg/day) or/and intramuscular vitamin $B_{12}$ (100 ig/day) for 4 weeks. Initially vitamin $B_{12}$ was given daily for a week followed by alternate day administration and then twice a week injection. Proper dietary advice was given in all cases. Three patients, who were severely anemic also, received blood transfusions. Antibiotics were administered in infective cases. Follow-up of patients showed improvement in all cases except one. The child who succumbed was severely malnourished with signs of multiple vitamin deficiency and bronchopneumonia.

**Discussion**

Deficiency of vitamin $B_{12}$ and folate most commonly results in megaloblastic anemia. All Megalo-blastic anemias are characterized by ineffective erythropoiesis, a kinetic term that describes active erythropoiesis with premature death of cells, a decreased output of RBCs from the bone marrow, and, conse-quently, anemia.\textsuperscript{24}

Megaloblastic anemia is a distinct type of anemia characterized by macrocytic RBC’s and typical morphological changes in RBC precursors. The precursors are larger than the cells of same stage and maturation and exhibit disparity in nuclear-cytoplasmic maturation. Both vitamin $B_{12}$ and folic acid are required in the synthesis of nucleoproteins; at the cellular level with resultant impairment of DNA synthesis and to a lesser extent, RNA and protein.

Children usually present with generalized weakness, fatigue, failure to thrive, or irritability. Other common findings include pallor, glossitis, vomiting, diarrhea, icterus, paraesthiases, hypotonia, seizures, tremors, developmental regression, neuropsychiatric changes, hemorrhages etc.\textsuperscript{24}

Megaloblastic anemia presents with protein manifestations as experienced in our study (Table 1). Bleeding most likely due to thrombocytopenia was noticed in 12% of patients. An earlier series documented bleeding in 17-20% of patients in megaloblastic anemia.\textsuperscript{67} Hemorrhagic

emergencies like intracranial bleeding and gut bleeding though not well appreciated in this disease have been rarely seen. Thrombocytopenia is believed to be due to impaired DNA synthesis resulting in ineffective thrombopoiesis. Icterus, not an infrequent feature in this disease was noticed in seven children (14%) in our study. It is explainable on the basis of decreased life span of RBCs and to premature destruction of developing megaloblasts in the marrow. Three children in our study presented with infantile tremor syndrome, a syndrome often associated with megaloblastic anemia due to nutritional vitamin B12 deficiency. Hyper-pigmentation of dorsum of hands and fingers though considered an important diagnostic sign for this disease was witnessed in only five children. The presence of fever in 52% of patients was significant, the commonest cause being infection to which the individual is much more susceptible in this disease due to impaired intracellular killing of ingested bacteria by neutrophils and macro-phages.

Thrombocytopenia was reported in 30% cases and leucopenia in 14% cases in our study. Megaloblastic anemia is an important cause of cytopenias (pancytopenia and bacute) but to the best of our knowledge, there are not many studies quoting its incidence. An earlier series reported an incidence of pancytopenia in 43.8% and bacute in 80.5% cases. The varying results in the two series could be due to the difference in the duration of anemia which is proportional to the development of cytopenias. It is generally believed that as severity of anemia increases, thrombocytopenia develops followed by neutropenia. The trends of serum levels of B12 and folate acid though done in only 29 cases clearly revealed predominance of B12 deficiency. Relative prevalence of cobalamin and folate deficiency in cases with megaloblastic anemia has been a subject of some debate. The studies in early sixties showed that folate deficiency was more prevalent, a trend similar to one observed in developed countries. However, compared to developed countries cobalamin deficiency was more common in India. Over the last four decades, the proportion of cases having cobalamin deficiency appears to have increased. This increase in cobalamin deficiency appears to be a global phenomenon as the recent reports appearing from other developing countries indicate. In a Mexican study on preschool children no folate deficiency was seen, but 41% had cobalamin deficiency. A Zimbabwean study on megaloblastic anemia (including adults and children) reported cobalamin deficiency being three times more common than folate deficiency. Out of 29 cases in which serum levels of vitamin B12 and folate levels were estimated, 9 cases had low levels of vitamin B12, while one case had pure folate deficiency and 12 cases showed combined deficiency. In our study, folate deficiency was not as low as reported by others. We feel that this changing trend might be related to National Nutritional Anemia Prophylaxis Program introduced in 1970 and revised to National Nutritional Anemia Control Program in 1991, in which 5 mg of folic acid is given with iron to all pregnant women. Polate stores at birth would generally be normal in children of these mothers. It could be due to poor nutritional status of children, mothers and vegetarian habits. Seven patients who had normal B12 and folate levels inspite of narrow megaloblastosis could be due to administration of vitamins by private practitioners before admission to the hospital though such history was not available. Other less common manifestations resulting from deficiency of these hematopoietic micronutrients in children include neuro-developmental effects and abnormal movements. Neural tube defects result from deficiency in mothers during pregnancy. Bone loss resulting in osteopenia, osteoporosis and pathological fractures and cardiovascular effects predisposing to coronary artery disease are observed in adults and elderly patients.

Conclusions

On the basis of observations made in this study, it is concluded that in any malnourished and anemic child presenting with bleeding manifestations, a strong suspicion of megaloblastic anemia should be entertained. Anemia is not the only problem in these children, as is evident from the finding of neutropenia and thrombocytopenia. Additionally cobalamin deficiency appears to be emerging as a significant contributor to nutritional megaloblastic anemia.
